ABSTRACT

12 Argo profiling floats initiated a revolution in observational physical
13 oceanography by providing numerous, high-quality, global, year-round in situ
14 (0–2000 dbar) temperature and salinity observations. Here, we use Argo’s
15 unprecedented sampling of the Southern Ocean during 2006 – 2013 to de-
16 scribe the position of the Antarctic Circumpolar Current’s Subantarctic and
17 Polar fronts, comparing and contrasting two different methods for locating
18 fronts using the same data set. The first method locates three fronts along dy-
19 namic height contours, each corresponding to a local maximum in vertically
20 integrated shear. The second approach locates the fronts using specific fea-
21 tures in the potential temperature field, following Orsi et al. (1995). Results
22 from our analysis of Argo data are compared to those from Orsi et al. (1995)
23 and other more recent studies. Argo spatial resolution is not adequate to re-
24 solve annual and interannual movements of the fronts on a circumpolar scale,
25 since they are on the order of 1° latitude (Kim and Orsi 2014), smaller than
26 the resolution of the gridded product analyzed. Here, Argo’s four-dimensional
27 coverage of the Southern Ocean equatorward of $\sim 60^\circ\text{S}$ is used to quantify
28 variations in heat and freshwater content there with respect to the time-mean
29 front locations. These variations are described in the Southern Ocean and in
30 regions between fronts during 2006 – 2013, considering both pressure and
31 potential density ranges (within different water masses) and relations to wind
32 forcing (Ekman upwelling and downwelling).

33 **1. Introduction**

34 Over the last three decades, the Southern Hemisphere climate has experienced dra-
35 matic changes: growth of the Ozone Hole (Hofmann et al. (1997); WMO (2011);
36 <http://www.nature.com/nature/focus/ozonhole/>), increased melting of the West Antarctic ice-
37 sheet (Ding et al. 2011; Rignot et al. 2014), overall thinning of the Antarctic ice-shelf (Paolo
38 et al. 2015), stronger winds (Marshall 2003; Thompson et al. 2011), and ocean warming (Gille
39 2008; Sutton and Roemmich 2011; Roemmich et al. 2015). The Southern Ocean warming and
40 freshening of water masses (Böning et al. 2008; Johnson et al. 2008; Purkey and Johnson 2010;
41 Meijers et al. 2011; Purkey and Johnson 2013) may be related to regional trends in sea ice extent
42 (Holland and Kwok 2012) or ice sheet melt (Jacobs and Giulivi 2010), and may also drive ice
43 sheet melting by ocean advection of heat (Rignot et al. 2013; Schmidtko et al. 2014; Alley et al.
44 2015). Because of its large heat capacity and influence on the Meridional Overturning Circulation
45 (MOC), the Southern Ocean is not only key for heat and freshwater redistribution in the global
46 climate system (Lumpkin and Speer 2007; Marshall and Speer 2012; Watson et al. 2014), but also
47 for the global atmosphere-ocean carbon budget (Sabine 2004; Boutin et al. 2008; Le Quere et al.
48 2009; Ito et al. 2010; Sallee et al. 2012). A quarter of all anthropogenic CO₂ emissions have
49 been captured in the Southern Ocean, with a main contribution by transformation of water masses
50 within the Antarctic Circumpolar Current and their subsequent sinking below the surface (Sabine
51 2004; Ito et al. 2010).

52 The Antarctic Circumpolar Current (ACC), the world's largest current, is the main feature of the
53 Southern Ocean and is dynamically connected with the MOC, which ventilates deep and bottom
54 portions of the Pacific, Atlantic, and Indian oceans (Lumpkin and Speer 2007; Johnson 2008;
55 Marshall and Speer 2012). Also, the ACC circulation blends together water masses formed in

56 different basins (Rintoul et al. 2001; Van Sebille et al. 2013). The ACC is not a smooth, large-
57 scale flow. Rather, most of its transport is concentrated in a series of well-separated fronts (Orsi
58 et al. 1995; Sallée et al. 2008; Sokolov and Rintoul 2009a,b; Thompson et al. 2010; Thompson
59 and Sallee 2012; Kim and Orsi 2014). These features separate regions with distinct temperature
60 and salinity signatures and are associated with deep-reaching jets and subduction or upwelling
61 of different water masses. In a landmark paper, Orsi et al. (1995) (hereon OWN95) describe
62 average properties of the fronts using station data from multiple synoptic transects. Three fronts
63 are identified between the Southern Boundary of the ACC and the Subtropical Front to the north:
64 the Southern ACC front, the Polar Front, and the Subantarctic Front. Initially the presence of
65 multiple cores in these ACC fronts was not detected, given the coarse meridional spacing of station
66 data, but has since been revealed (Sokolov and Rintoul 2002, 2007, 2009a; Anilkumar et al. 2006).
67 Numerous regional analyses of the ACC frontal structure are based on in situ oceanographic profile
68 or surface (i.e. surface drifter or satellite) data. Most common domains for these studies are in
69 Drake Passage (Cunningham and Pavic 2007; Firing et al. 2011; Renault et al. 2011), around
70 the Kerguelen Plateau (Sparrow et al. 1996; Belkin and Gordon 1996; Park et al. 2009, 2014;
71 Tarakanov 2014), and along the ACC sector south of Australia and New Zealand (Belkin and
72 Gordon 1996; Sokolov and Rintoul 2002; Budillon and Rintoul 2003; Sokolov and Rintoul 2007).
73 Additional analyses have been carried out south of Africa (Belkin and Gordon 1996), and in the
74 South Atlantic (Peterson and Whitworth 1989; Boehme et al. 2008; Billany et al. 2010), Indian
75 (Belkin and Gordon 1996; Anilkumar et al. 2015), and Eastern Pacific (Tarakanov 2011) sectors
76 of the Southern Ocean.

77 Beside hydrographic data (OWN95, Böning et al. (2008)), surface observations from satellites
78 have been widely used to describe the ACC fronts on a global (circumpolar) scale (Gille 1994;
79 Dong et al. 2006; Sallée et al. 2008; Sokolov and Rintoul 2009a,b; Thompson and Sallee 2012;

80 Kim and Orsi 2014). Sallée et al. (2008) and Sokolov and Rintoul (2009a,b) combine the mean
81 dynamic topography from in situ profiles (referenced to 1500 and 2500 dbar respectively), with
82 altimetry data to study both the time mean and variability of the fronts' location through a contour-
83 based approach (Sokolov and Rintoul 2007, 2009a,b). The applicability of this method has been
84 debated (Graham et al. 2012; Thompson and Sallee 2012; De Boer et al. 2013; Gille 2014). Gra-
85 ham et al. (2012) find that gradient maxima in the sea surface height field are the most reliable
86 indicator of a front's location, while using sea surface height (SSH) contours can give misleading
87 results for the temporal variability of the frontal position. Yet Chapman (2014) shows that the
88 contour-based approach is more accurate than other methods (i.e. gradient, PDF and wavelet/HOS
89 methods) at all signal to noise ratios, when applied to a synthetic SSH field. Finally, SSH anoma-
90 lies of meandering jet-like features are associated with non-Gaussian probability density function
91 (Thompson and Demirov 2006), allowing study of ACC fronts with altimetry observations (Shao
92 et al. 2015). No estimates of the mean dynamic topography are required, ensuring that any tem-
93 poral variability in frontal location is unaffected by large-scale SSH changes.

94 Kim and Orsi (2014) find large year-to-year meridional fluctuations in frontal locations in the
95 southeast Pacific during 1992–2011 using altimetry data and a contour-based approach (with a
96 mean dynamic topography that combines GRACE and Argo observations). These fluctuations are
97 related mostly to the El Niño-Southern Oscillation (ENSO) and in part to the Southern Annular
98 Mode (SAM), with no apparent seasonal cycles or long-term trends detected in this region. In con-
99 trast, in the southeast Indian ocean fronts shift to the south in summer and to the north in winter.
100 Also, a long-term southward drift of the ACC fronts is observed in the Indian sector. This move-
101 ment is hypothesized to be a response to the poleward expansion of the Indian subtropical gyre.
102 Gille (2014) finds no long-term trend in the zonally averaged ACC transport latitude index (i.e.
103 based on the (zonal) transport-weighted average latitude) from altimetry data, a weak sensitivity

104 to the Southern Annular Mode, and no correlation with ENSO. Also, Gille (2014) suggests that
105 the poleward trend in SSH contours might be associated with large-scale changes in SSH due to
106 a warming ocean more than with localized shifts in frontal positions. Recently, Shao et al. (2015)
107 also show that the ACC as a whole and on regional spatial scales does not exhibit significant
108 meridional trends between 1993 and 2012, and is relatively insensitive to climate mode-induced
109 variability except in the East Pacific (where they find correlation between the basin-averaged Sub-
110 antarctic and Polar fronts' position and SAM, with a positive SAM corresponding to a northward
111 shift) and south of Australia (with the Polar Front shifting southward during positive SAM).

112 Since the ACC fronts are linked to ocean dynamics (current strength), thermodynamics (sites of
113 water mass transformation; OWN95), and the pattern of upwelling/downwelling associated with
114 the closure of the global overturning circulation (Marshall and Speer 2012), the structure of the
115 fronts is closely related to the distribution of heat and freshwater in the Southern Ocean. Analysis
116 of in situ data shows how coherent warming and freshening trends in the Southern Hemisphere ex-
117 tend deeper than 1,000 m and are partially related to water mass changes within the ACC (Böning
118 et al. 2008). Altimetry data, too, reveal similar changes in the ACC (Meijers et al. 2011), with
119 diabatic processes contributing to cooling, while playing a key role in observed freshening. Dur-
120 ing 2006 – 2013, in the upper 2000 dbar of the global ocean sampled by Argo floats, the Southern
121 Hemisphere ocean is the main recipient of heat from global warming, with regional patterns indi-
122 cating cooling south of 50°S in the Pacific (Roemmich et al. 2015). Multidecadal warming and/or
123 freshening in the ACC is also reported (Aoki et al. 2005; Sprintall 2008; Naveira Garabato et al.
124 2009; Tarakanov 2011; Kobayashi et al. 2012; Schmidtko and Johnson 2012; Close et al. 2013;
125 Yang and He 2014), with some exceptions related to regional dynamics, such as the influence of
126 the Agulhas Rings south of Africa (Swart and Speich 2010).

127 Here we use Argo’s unprecedented sampling of the Southern Ocean (Roemmich et al. 2015)
128 during 2006–2013 to describe the position of the ACC Subantarctic and Polar fronts based on
129 subsurface water properties. We detect fronts using two different methods, and compare with
130 results from OWN95 and other more recent studies. Argo spatial resolution is not adequate to
131 resolve annual and interannual movements of the fronts locally, since they are on the order of 1
132 degree latitude (Kim and Orsi 2014). Yet Argo four-dimensional coverage of the Southern Ocean
133 equatorward of $\sim 60^\circ\text{S}$ can be used to identify fronts and quantify heat and freshwater content
134 variations in the Southern Ocean. Here, we describe changes in heat and freshwater content in the
135 Southern Ocean (within the Argo domain) and regions in between the mean front locations during
136 2006–2013, considering both pressure and potential density ranges (different water masses) and
137 relations to wind forcing (Ekman upwelling and downwelling).

138 We describe data and methods in Section 2. We find frontal locations using Argo data, com-
139 paring a Dynamic Height (DH) contour approach (Section 3a) with a potential temperature (θ)
140 feature-based method (Section 3b). We relate these results from Argo to the findings of OWN95
141 and more recent studies and discuss the θ -S properties at the fronts (Section 3c). Also, we analyze
142 changes in heat and freshwater content from 2006–2013 in the Southern Ocean (within the Argo
143 domain) and for different regions in between fronts, discussing the relation between θ -S variability
144 and wind forcing (Section 4). We summarize and conclude in Section 5.

145 **2. Data and methods**

146 *a. Data.*

147 Argo temperature and salinity profiles provide global in situ (0 – 2000 dbar) ocean observations,
148 except on continental shelves, in marginal seas, and, until recently, seasonally ice-covered regions

149 (Klatt et al. 2007), with unprecedented sampling of the Southern Ocean (Roemmich et al. 2009).
150 We use objectively mapped monthly fields (Roemmich and Gilson 2009) on a 1×1 degree grid
151 from 64.5°S - 64.5°N constructed from Argo temperature and salinity observations during 2006 –
152 2013, after quality control and adjustment of pressure bias. In order to test how the mapping may
153 affect the analysis in lightly sampled regions, we check that the resulting frontal locations are
154 consistent with the original profile data (see Supplemental material).

155 *b. Methods to locate the fronts.*

156 ACC fronts are associated with strong gradients in temperature and salinity, and with deep-
157 reaching jets (OWN95). Here, we compare two methods to identify the Subantarctic and Polar
158 fronts of the ACC in a gridded Argo product. The first approach locates fronts along Dynamic
159 Height (DH) contours that correspond to local maxima in vertically integrated shear (Section 2b.1).
160 The second approach follows the fronts along specific features in the potential temperature field
161 (Section 2b.2), similarly to OWN95. Results (Section 3) show the locations of the fronts as prob-
162 ability of occurrence (Figs. 3, 4) and time-averaged during 2006 – 2013 (Figs. 2b, 5, 6, 10), once
163 the annual variability is removed from the Argo fields (annual displacements of the fronts are not
164 resolved by Argo). The DH and feature-based methods are in overall good agreement with each
165 other, and only the DH approach is used in the second part of the manuscript.

166 1) FRONTS ALONG DYNAMIC HEIGHT CONTOUR LINES.

167 Fronts are characterized by strong geostrophic currents. To find those DH contours that are
168 aligned with fronts, we consider a set of DH bins and count (for each) the number (N , monthly) of
169 co-located local maxima in 0 – 1975 dbar integrated shear (within the Argo domain in the Southern
170 Ocean), i.e. local maxima in geostrophic velocity amplitude at the surface from DH referenced

171 to 1975 dbar. The sum of N (in time) is characterized by three peaks, each identifying a different
 172 DH range (Fig. 1). Each DH range is associated with a different front (e.g. front i), and a contour
 173 (DH_i^*) within that range is assigned to the front (red lines in Fig. 1). DH_i^* is the time average DH
 174 of DH bins (within range i) that correspond to monthly local peaks in N . Thus front i is described
 175 using $DH_i^* = \overline{DH_{N_{i_{\max}}}(t)}$, where $DH_{N_{i_{\max}}}$ is associated with the maximum N within the DH range
 176 i (i.e. $N_{i_{\max}}$) for a given month t . The standard error of DH_i^* is related to the time variability of the
 177 DH bin that corresponds to $N_{i_{\max}}$ (i.e. $DH_{N_{i_{\max}}}$), and is small (Fig. 1). Finally, the DH bin size in
 178 Fig. 1 is $.5 \text{ m}^2\text{s}^{-2}$. Varying this dimension between $.15$ and $.7 \text{ m}^2\text{s}^{-2}$ yields DH^* values that are
 179 generally comparable to one another within errorbars.

180 Based on their position and θ -S properties, the three fronts identified here are named, from north
 181 to south (i.e. decreasing values of DH contours): Northern Subantarctic front (nSAf), Southern
 182 Subantarctic front (sSAf), and Polar front (Pf). These names do not necessarily correspond to
 183 those in other studies that describe a different number of cores for each ACC front (e.g. Sokolov
 184 and Rintoul (2002, 2007, 2009a); Anilkumar et al. (2006)). The spatial scales of the gridded Argo
 185 product are larger than available altimetry products and cannot resolve all the cores of the ACC
 186 fronts. Also, Argo data still undersample the southern fronts of the ACC, where seasonal sea ice
 187 was once a hurdle for deployments (Klatt et al. 2007).

188 2) FRONTS ALONG SPECIFIC FEATURES OF THE POTENTIAL TEMPERATURE FIELD.

189 Based on the description by OWN95 (their Table 3) and consistent with subduction and/or shoal-
 190 ing of water masses, we locate fronts in the Argo dataset along characteristic θ features (Table 1).
 191 That is, we locate a front at the intersection between a constant θ^* surface and (for the SAf) a
 192 pressure level or (for the Pf) a θ -extremum surface (e.g. the maximum θ deeper than 800 dbar).
 193 We compare frontal locations by OWN95 with those estimated from Argo data using θ^* values

194 consistent with OWN95 (see θ^* values in Table 1 and resulting frontal locations later in Fig. 5).
195 OWN95 do not describe two branches of the Subantarctic Front, but provide a θ range (at 400
196 dbar) to characterize it: we associate the minimum and maximum values of this θ range with the
197 sSAf and nSAf respectively. Also, we compute (Table 1) θ^* values along the frontal locations
198 from the DH contour approach (i.e. the circumpolar and time average of θ at the x, y intersection
199 between the DH_i^* contour associated with front i and the pressure level or θ -extremum surface
200 of interest), and compare the two (DH- versus θ -based) methods (Fig. 6). This procedure for
201 local comparisons is motivated by the possibility of using a θ -contour as boundary between water
202 masses (OWN95) and by an overall circumpolar agreement between the DH- versus θ - (i.e. water
203 mass-) based approach. Such agreement is seen in how the average θ profiles along the DH-based
204 Pf, sSAf, and nSAf separate regions where the water-mass volumes in the Southern Ocean (within
205 the Argo domain) peak (Fig. 2a), i.e. where θ values are fairly homogeneous and characteristic
206 of that region and pressure level (regions at the boundary of the domain are not well represented
207 in Fig. 2a). These peaks, although sometimes weak (e.g. between the sSAf and the nSAf), have a
208 coherent structure in the p - θ_{bin} plane, consistent with a circumpolar frontal structure of the ACC
209 that can be described using θ -criteria (OWN95). Yet the peaks are not observed at all individual
210 longitudes, partially due to the resolution of the data (especially where different fronts are close to
211 one another) and the limited southward extent of the Argo domain.

212 We evaluate a set of θ features or criteria for each front (see Table 1 and Supplemental material;
213 in this manuscript, the word "criteria" is used in the context of the θ -method to locate the fronts,
214 which is based on, but does not strictly follow, the characterization in OWN95). Here we focus on
215 those criteria that align best with results from the DH contour method, i.e. yield the best overall
216 agreement both in circumpolar location, and θ -S properties at different pressure levels. These
217 features (Table 1, in bold) are identified by θ^* values of the maximum θ (hereon $\max(\theta)$) deeper

218 than 800 dbar (to locate the Pf), and of θ at 400 dbar (to locate the sSAf and the nSAf). For the
219 Pf, the $\max(\theta)$ criterion at $p \geq 800$ dbar does not strictly follow the characterization in OWN95.
220 OWN95 describe the Polar Front as being south of where $\theta_{max} > 2.2^\circ\text{C}$ at $p \geq 800$ dbar (their Table
221 3), with θ_{max} a local vertical maximum. In the Argo dataset, this θ_{max} is generally shallower than
222 800-850 dbar (not shown), hence the $\max(\theta)$ at $p \geq 800$ dbar criterion (Table 1) captures θ_{max} only
223 at some longitudes, and constrains θ at 800 dbar elsewhere (since $\max(\theta)$ is the largest value of θ
224 in a pressure range and not necessarily a local vertical maximum).

225 The θ_{max} at depth is related to a θ_{min} (i.e. θ local vertical minimum) in the upper ocean, which
226 has been used to characterize the Polar front (OWN95), and is described here as an alternate θ
227 criterion, although it does not align with the DH-based Pf as well as an isotherm along the $\max(\theta)$
228 at $p \geq 800$ dbar does. This θ_{min} is present only during summer. Hence, with year-round data from
229 Argo, we favor the deeper criteria in this analysis. Also, the θ_{min} is generally shallower than 200
230 dbar (not shown), hence the minimum θ (hereon $\min(\theta)$) at $p \leq 200$ dbar criterion we use (Table
231 1) is equivalent to the characterization in OWN95 (their Table 3), except that it includes profiles
232 where the θ_{min} is not present (e.g., winter-time profiles; common in Argo data, but not previous
233 hydrographic data). We discuss other θ and S features along the fronts and how they align with
234 the DH-based approach in the Supplemental material.

235 *c. Freshwater estimate from Argo salinity anomaly.*

236 Freshwater anomalies (FW) for a region of interest, are estimated as centimeters of freshwa-
237 ter over the area of the Southern Ocean in the gridded Argo domain ($A_{SO} = 6.001 \cdot 10^{13} \text{m}^2$),
238 i.e. $\text{FW} = V_{\text{FW}} / A_{\text{SO}}$. The freshwater volume, V_{FW} , is defined as the amount of freshwater that
239 would need to be added to or removed from a reference volume V_m (with salinity S_m), in or-
240 der to obtain salinity S_i (at timestep i), without modifying the salt content of the water, i.e.

241 $V_{FW} = \int \left(\frac{S_m}{S_i} - 1 \right) dV_m$. Here, V_m is the volume associated with the Argo grid in the region
242 and pressure levels of interest, and S_m and S_i are the corresponding time mean and time changing
243 salinity.

244 **3. The Polar and Subantarctic fronts of the ACC from Argo**

245 *a. Fronts along dynamic height contour lines.*

246 The location of the Pf cannot be determined everywhere in the Pacific sector of the Southern
247 Ocean, since, at some longitudes, the Pf is poleward of the Argo domain and the gridded maps. The
248 Argo Pf shows good agreement with (i.e. only slight differences from) OWN95's estimate in Drake
249 Passage (Fig. 3, red #1), between the Maurice Ewing Bank (Fig. 3, red #2) and the Atlantic Ridge
250 (Fig. 3, red #4), between 150 – 170°E and 175 – 120°W in the Pacific, and between 35 – 55°E and
251 100 – 115°E in the Indian sector (Fig. 3). In other regions, the Argo Pf is further south than the
252 previous estimate of OWN95 and is more consistent with the middle branch of the Polar Front in
253 Sokolov and Rintoul (2009a) which generally agrees well with our Argo Pf circumpolar location.
254 We observe a large southward shift in the Argo Pf position relative to OWN95 at the Maurice
255 Ewing Bank (Fig. 3, red #2; consistent with Sokolov and Rintoul (2009a) and Kim and Orsi
256 (2014)), in the eastern Atlantic and between 115 – 145°E (consistent with Sokolov and Rintoul
257 (2009a) and different from Kim and Orsi (2014)), and around the Kerguelen Plateau (Fig. 3, red
258 #6), with the Argo Pf flowing just north of the Fawn Trough (Fig. 3, red #7). In this region, our
259 results are consistent with Sparrow et al. (1996) and Sokolov and Rintoul (2009a), but neither Kim
260 and Orsi (2014) nor Park et al. (2014) (discussed further in Section 3b).

261 We find two cores of the Subantarctic Front in the Argo dataset, the sSAf and the nSAf. Along
262 most of their circumpolar path, these two cores are consistent with the southern and middle branch

263 of the Subantarctic Front in Sokolov and Rintoul (2009a), respectively, with the largest differences
264 in the Pacific Ocean, east of the Campbell Plateau (Fig. 3, red #9). Here, the nSAf sharply veers
265 northward to follow the bathymetry and comes back to the south around 180°E, consistent with the
266 Subantarctic Front in Böning et al. (2008) and Kim and Orsi (2014), and with the northern (rather
267 than the middle) branch of the Subantarctic Front in Sokolov and Rintoul (2009a). Similarly,
268 the nSAf sharply veers northward at the East Pacific Rise (Fig. 3, red #14), again in agreement
269 with Böning et al. (2008) and the northern (rather than the middle) branch of the Subantarctic
270 Front in Sokolov and Rintoul (2009a), but not Kim and Orsi (2014), where no sharp northward
271 meandering is observed. In general, the Argo sSAf traces more closely (than the nSAf) the location
272 of the Subantarctic Front in OWN95, except in the western Atlantic (near South America), in the
273 Indian Ocean eastward of 70°E, and in the eastern Pacific. Also, in OWN95, both the Subantarctic
274 and Polar fronts cross the Pacific-Antarctic Ridge via the Udinsev Fracture Zone (Fig. 3, red #11).
275 Results here suggest that only the Pf does (Fig. 3, red #11), in agreement with Kim and Orsi
276 (2014) and Sokolov and Rintoul (2009a), while the sSAf goes through the Eltanin Fracture Zone
277 (Fig. 3, red #12) and the nSAf through the Menard Fracture Zone (Fig. 3, red #13). However, the
278 Argo climatology resolution may be a limitation when describing the front position in relation to
279 these narrow bathymetric features.

280 The location of the ACC fronts from Argo agrees well with local maxima of the zonal and merid-
281 ional baroclinic geostrophic transport in the upper 1975 dbar from Argo (Fig. 4, with velocities
282 referenced to 1975 dbar). Such agreement is expected on the overall circumpolar scale (since DH_i^*
283 contour values are chosen based on Argo integrated shear on a circumpolar scale, Section 2b.1)
284 and Fig. 4 shows that it holds also locally. As an example, the northward meandering of the nSAf
285 east of the Campbell Plateau (Fig. 3, red #9) and at the East Pacific Rise (Fig. 3, red #14) aligns

286 with a pattern of stronger meridional velocities (Fig. 4b). The strongest integrated transport is in
287 the western Indian ocean, associated with the Agulhas retroflexion (Fig. 4a).

288 *b. Fronts along specific features of the potential temperature field.*

289 The Pf location using θ^* values by OWN95 in the Argo θ field (Section 2b.2) is in overall
290 agreement with OWN95, but regional discrepancies between the shallower and deeper criterion
291 are large between $50 - 80^\circ\text{E}$, $\sim 115 - 140^\circ\text{E}$, and $\sim 170 - 150^\circ\text{W}$ (Fig. 5). Around the Kerguelen
292 Plateau (i.e. $50 - 80^\circ\text{E}$), a Pf criterion on the $\max(\theta)$ deeper than 800 dbar yields a path of the
293 Pf that is south compared to the upper ocean $\min(\theta)$ criterion (Fig. 5), except for some of the
294 individual Argo profiles that align with the shallower criterion between $70 - 80^\circ\text{E}$ (Fig. S1c in
295 the Supplemental material). These profiles do not fall on a circumpolar path (Fig. S1c), and the
296 corresponding θ field yields large errorbars for the Pf from the $\max(\theta)$ -criterion in Fig. 5 (between
297 $70 - 80^\circ\text{E}$). In summary, the shallower criterion suggests a Pf location (in the region of interest)
298 that is to the north compared to following θ^* along $\max(\theta)$ deeper than 800 dbar. The shallower
299 criterion is based on a θ_{min} (OWN95) that is present only during summer. With year-round data
300 from Argo, we favor the deeper criteria in this analysis.

301 Using 2°C as the θ^* value for the $\min(\theta)$ -based Pf (as in Fig. 5) is consistent with Table 3 in
302 OWN95 and is similar to the criterion in Park et al. (2014) (who consider θ_{min} in the 100 – 300
303 m depth range), but the resulting front location is different from both of the other studies. In the
304 gridded Argo product used here, the 2°C contour of the minimum θ in the upper 200 dbar (i.e.
305 a $\min(\theta)$ -based Pf) sharply veers northward at the plateau (65°E , Fig. 5), while in OWN95 their
306 Polar Front gently veers northward between 55 and $\sim 62.5^\circ\text{E}$ (Fig. 5), and in Park et al. (2014),
307 the 2°C isotherm that corresponds to their Polar Front veers northward around 71°E (their Fig. 5).

308 A northward change in direction, west of 70°E , as in the gridded Argo product here, is consistent
309 with individual Argo profile observations (see Supplemental material).

310 The sSAf and the nSAf locations using θ^* values by OWN95 in the Argo θ field (Section
311 2b.2) align with the Subantarctic Front in OWN95 only in few sectors of the ACC (e.g. around
312 110°E , Fig. 5). At other longitudes, one of them may be close to the previous estimate but not
313 the other (e.g. the sSAf around 175°W) or they are both far (generally to the north, e.g. in the
314 Atlantic basin). Sectors of the Southern Ocean where Argo fronts based on θ^* values in OWN95
315 are equatorward of the position in OWN95 indicate that the regional Argo climatology at the
316 pressure levels of interest (for the criteria) is colder than previous observations (collected between
317 1976 – 1990 for sections in the Atlantic Ocean, and 1974 – 1977 in the western Indian basin).
318 Unfortunately, a regional long term trend cannot be estimated due to the sparsity of observations
319 in the Southern Ocean for the period previous to Argo. The simple comparison (here) of the Argo
320 versus OWN95 frontal locations may be aliased by interannual and decadal variability, as well as
321 by differences between the two datasets (temporally and spatially distributed Argo profiles versus
322 synoptic, mostly summertime sections) and methods. Yet Argo profile data (with no annual cycle
323 removed, Fig. S1b) that follow the 2°C shallow criterion lay north of the Polar Front location in
324 OWN95 in the same ACC sectors ($140 - 170^{\circ}\text{E}$ and $175^{\circ}\text{E} - 120^{\circ}\text{W}$) as for the gridded data (with
325 the annual cycle removed, Fig. 5). Also, ECMWF ERA-Interim Sea Surface Temperature (SST)
326 shows a statistically significant linear decrease between 1979 and 2013 in the general ACC Pf
327 region at those longitudes (not shown), consistent with a local long term cooling of the upper ocean
328 and with the $\min(\theta)$ -based Argo Pf being equatorward of the Polar Front in OWN95. Regional
329 cooling is not inconsistent with the overall warming of the Southern Ocean observed for the last
330 few decades and during the Argo period (Roemmich et al. 2015).

331 We compute θ^* values (analogous to those of OWN95) along DH contours that identify fronts
332 as in Section 2b.1 (Table 1). Resulting frontal locations are in overall good agreement with the
333 DH contour approach (Fig. 6), showing how the two methods, described in Section 2b.1 and 2b.2,
334 align regionally (the agreement on a circumpolar scale is discussed in Section 2b.2).

335 Also, the θ^* value of the upper ocean $\min(\theta)$ computed along the DH-based Argo Pf, agrees,
336 within errorbars, with the value in Sokolov and Rintoul (2009a), but not OWN95 (Table 1). How-
337 ever, the value of the $\max(\theta)$ at $p \geq 800$ dbar along the DH-based Argo Pf agrees with both the
338 previous findings, as does $\theta(400$ dbar) along the DH-based Argo nSAf (Table 1). In contrast,
339 along the DH-based Argo sSAf, $\theta(400$ dbar) differs from both OWN95 and Sokolov and Rintoul
340 (2009a) (Table 1). A main advantage in computing θ^* values along DH- (i.e. streamline-) based
341 fronts here resides in having both the streamfunction and the θ field from the same well-resolved
342 (Argo) dataset and for the same time period (2006 – 2013).

343 Argo fronts from θ criteria that generally agree best with the DH contour method (in bold
344 in Table 1, with θ^* values computed along DH-based fronts), still fail to align with it in a few
345 regions (Fig. 6), suggesting that, in specific sectors of the Southern Ocean, a combination of
346 different criteria (Table 1 and Supplemental material) may be appropriate to locate the fronts more
347 accurately when using a feature-based approach. In the eastern Pacific, the nSAf (from θ) hits
348 the South American coast, rather than flowing through Drake passage. This may be related to how
349 formation of Subantarctic Mode Water impacts the θ -field in the region and can be corrected using
350 a regional criterion on θ at 600–dbar (see Supplemental material). Around 90°E, the θ -based
351 sSAf and nSAf flow south of the corresponding DH-fronts (a 600–dbar criterion for θ would
352 reduce this departure too). In the Atlantic basin, the sSAf and nSAf flow north of the DH-fronts
353 (reduced applying a salinity criterion in the region).

354 *c. θ -S properties along the fronts: time mean and interannual variability.*

355 Time-mean θ -S diagrams along the Pf and the nSAf are similar using the DH contour method
356 versus θ criteria with θ^* values by OWN95 (Fig. 7a). However, the sSAf from the latter shows
357 θ -S properties in between the DH-based sSAf and nSAf (Fig. 7a).

358 The Pf θ -S diagram from Argo shows a θ minimum (θ_{min}) in the upper 200 dbar and a θ
359 maximum (θ_{max}) at depth (Fig. 7b), as described in OWN95. However, the θ_{min} is colder than
360 2°C , and the θ_{max} is between 400 – 700 dbar, consistent with the description in Section 3b.

361 The θ^* values computed along the DH frontal locations yield fronts with θ -S properties that
362 agree well with the DH method (Fig. 7b). While this result is expected at the pressure level of
363 interest for the θ -criteria (since θ^* values are computed along DH-fronts), the overall agreement
364 of the θ -S curves is further evidence of how the two methods, described in Section 2b.1 and 2b.2,
365 are consistent with appropriate θ^* choices. Also, the difference in salinity arising from using one
366 approach versus the other for the SAf is consistent with the observed northward departures of
367 the θ -based sSAf and nSAf in the Atlantic compared to the DH-approach (Fig. 6), and could be
368 reduced by including a regional salinity criterion. Results in the rest of the manuscript are based
369 on the DH contour method.

370 θ -S properties of the Argo nSAf and Pf show interannual variability during 2006 – 2013 (Fig.
371 8). Deeper than 200 dbar, the nSAf was warmer and saltier in 2008 compared to 2011 (Fig. 8a),
372 while the Pf was colder and fresher in 2006–2009 compared to 2011–2013 (Fig. 8b). At these
373 pressure levels, changes in θ and S are mostly compensating in density. This is not the case for
374 the Pf θ_{min} in the upper 200 dbar, where θ -S properties were colder and saltier in 2006–2007
375 compared to 2010–2011 (Fig. 8b). Since the θ -S properties of interest are along a fixed DH
376 contour, θ -S anomalies must compensate in density in a vertically integrated sense.

377 **4. Heat and freshwater content in the Southern Ocean**

378 We describe changes in heat and freshwater content in different regions around the ACC. We
379 define these regions (within the Argo domain) based on the time mean location of the Polar, Sub-
380 antarctic, and Subtropical fronts (Section 3a; Fig. 2b). The SO region extends south of the STf,
381 n.nSAf is between the STf and the nSAf, SAf.nPf extends from the nSAf to the north of the Pf,
382 and Pf.s includes the Pf and south of it. The Subtropical front (STf) is used as our northernmost
383 boundary, and is located along the 12°C isotherm at 100 dbar (OWN95). Due to the time-constant
384 boundary for each region, frontal shifts may influence θ -S changes locally within the region. Yet
385 the effect on resulting circumpolar heat and freshwater anomalies may be small (e.g. meridional
386 displacements may be to the south at some longitudes and to the north at others (Shao et al. 2015)).
387 Also, interannual variability in frontal locations may not be large enough to be detected robustly
388 in Argo.

389 We describe interannual variability of heat and freshwater content in pressure ranges and density
390 classes (water masses) in Section 4a, and related θ -S anomalies in Section 4b. In Section 4c, we
391 discuss how wind-forced vertical advection (i.e. Ekman downwelling) causes isopycnals to deepen
392 in 2010 – 2012, contributing to the observed ocean warming signal.

393 *a. Heat and freshwater content interannual variability.*

394 The SO heat content (in the upper 1975 dbar) increased during 2006 – 2013 (Roemmich et al.
395 (2015) and Fig. 9a) with contributions from all three of the regions considered here, and especially
396 n.nSAf (red line, Fig. 9a). Most of this increase is confined to the top 1000 dbar (Fig. 9c,e), with
397 weaker signal between 1000 – 1500 dbar (Fig. 9g) and a positive anomaly in 2006 for the Pf.s
398 region between 1500 – 1975 dbar (Fig. 9i, blue line). At these pressure levels the SO anomaly

399 in 2006 and 2007 is smaller than the related standard error, while the n.nSAf heat content is
400 characterized by negative anomalies in 2006 – 2009 and positive later, as in shallower layers.

401 The SO freshwater anomaly in the upper 1975 dbar (computed as in Section 2c) is negative in
402 2009 and 2013, and positive in 2011–2012, with different contributions from different regions
403 (Fig. 9b). In n.nSAf, the FW anomaly is positive in 2006 – 2007 and 2011, and negative in
404 2012 – 2013, as a nearly linear decrease that dominates the SO signal in the upper 500 dbar
405 (Fig. 9d, red line) is added to increasing freshwater between 1000 – 1975 dbar (Fig. 9h,j), with
406 the transition occurring between 500 – 1000dbar (Fig. 9f). The SAf.nPf region too has different
407 phasing between the upper 500 dbar and the deeper levels, with a contribution to the SO signal that
408 is small in the shallowest layer, and larger at depth. Finally, Pf.s provides the smallest contribution
409 to the FW interannual variability in the SO, with the exception of the 2011 positive and 2013
410 negative anomalies (Fig. 9b, blue line), that are related to changes in shallower (Fig. 9d) and
411 deeper (Fig. 9f,h,j) layers, respectively. The yearly freshwater anomaly (in the upper 1975 dbar,
412 Fig. 9b) varies spatially in each region (Fig. 10). The 2006 – 2007 positive anomaly (Fig. 9b)
413 is dominated by variability in the Indian sector of n.nSAf, south of the nSAf in the central South
414 Pacific, and south of the STf in the South Atlantic (especially in 2007) (Fig. 10a-b). However, the
415 2011 – 2012 positive anomaly (Fig. 9b) is set by variability south of the nSAf in the South Indian
416 ocean, in n.nSAf and SAf.nPf in the central and eastern South Pacific and western (and eastern, in
417 2012) South Atlantic, and in the Pf.s region (in 2011) (Fig. 10f-g). The 2009 negative anomaly
418 (Fig. 9b) is dominated by the signal south of the nSAf in the South Indian ocean, south of the STf
419 in the central and eastern South Pacific and western South Atlantic, and in n.nSAf and SAf.nPf in
420 the eastern South Atlantic (Fig. 10d). Finally, the 2013 negative anomaly (Fig. 9b) is set by the
421 signal in the Indian sector of n.nSAf, south of the STf in the western and central South Pacific,
422 and south of the Pf in the central and eastern Atlantic and in the western Indian Ocean (Fig. 10h).

423 Overall warming during 2006 – 2013 is also observed for water masses in the potential density
424 (σ_θ) range $26.8 \leq \sigma_\theta \leq 27.7 \text{ kg m}^{-3}$ (Fig. 11, top panels), with a stronger signal for Subantarctic
425 Mode Water ($26.8 \leq \sigma_\theta \leq 27.0 \text{ kg m}^{-3}$). FW anomalies indicate freshening of water masses for
426 $27 \leq \sigma_\theta \leq 27.45 \text{ kg m}^{-3}$ (Fig. 11e), with positive anomalies also in 2006–2007 for $\sigma_\theta > 27.45$
427 kg m^{-3} . Also, the n.nSAf contribution to the SO signal for $\sigma_\theta > 27.0 \text{ kg m}^{-3}$ is a FW increase
428 during the Argo years, at all levels. In contrast, in the SAf.nPf and Pf.s regions, for $\sigma_\theta > 27.35$
429 kg m^{-3} , water masses are characterized by a positive FW anomaly in 2006, 2007 (for SAf.nPf),
430 and 2011 – 2012 (Fig. 11g-h).

431 Finally, the FW anomaly in the SAMW range $26.8 \leq \sigma_\theta \leq 26.9 \text{ kg m}^{-3}$ is negative at the end of
432 the time series and positive before that (Fig. 11e-f).

433 *b. θ -S property changes on isopycnals.*

434 Heat and freshwater changes in potential density classes described here (Fig. 11), are based on
435 mean isopycnal locations. Yet θ -S properties vary differently on the actual time-changing isopy-
436 cnals (Fig. 12 versus Fig. 13), with potential density decreasing in time on the mean isopycnal
437 location (Fig. 12i-l). The θ -S anomalies in Fig. 12a-h are not scaled by layer thickness, but are
438 consistent with heat and freshwater changes in Fig. 11, i.e. overall θ increase (Fig. 12a-d) and
439 S decrease (Fig. 12e-h) during 2006 – 2013, on most layers (except for salinity in the SAMW
440 range). On the actual isopycnal locations θ increases in time at all levels, only in the SAf.nPf and
441 Pf.s regions (Fig. 13c-d), and decreases for $\sigma_\theta < 27.3 \text{ kg m}^{-3}$ in the SO and n.nSAf (Fig. 13a-
442 b). Also, in SAf.nPf and Pf.s, salinity increases (rather than decreases) on most isopycnals (Fig.
443 13g-h), while, in the SO, it does so only for $\sigma_\theta > 27.3 \text{ kg m}^{-3}$ (Fig. 13e). We find no significant
444 salinity changes at such densities in n.nSAf (Fig. 13f).

445 *c. Ekman upwelling and downwelling, and pressure changes on isopycnals.*

446 We find an overall pressure increase on isopycnals in the Southern Ocean (Fig. 13i-l). In the
447 SO, n.nSAf and SAf.nPf regions, Argo pressure changes are consistent with a contribution from
448 wind-forced vertical advection (i.e. Ekman upwelling and downwelling, Fig. 14), estimated from
449 ECMWF ERA-Interim zonal and meridional momentum flux at the ocean-atmosphere interface.
450 The agreement holds only in 2007 – 2010 in n.nSAf and it breaks down in Pf.s (not shown), where
451 isopycnals shown in Fig. 14 (i.e. within the Southern Ocean Argo domain at each timestep) are
452 shallower and direct heat and freshwater exchanges with the atmosphere play a greater role than
453 dynamics. In Pf.s, isopycnals are also steeper and carry ventilation to great depths. In general,
454 when comparing between Argo pressure changes on isopycnals and wind forcing, diabatic con-
455 tributions are not the only mechanism at play besides vertical advection (e.g. lateral motion of
456 sloping isopycnals may also affect how pressure on isopycnals changes over time). These addi-
457 tional processes may explain some of the differences in pressure changes on isopycnals between
458 Argo and the estimate from ECMWF ERA-Interim (i.e. sign and/or amplitude differences in Fig.
459 14), along with the uncertainty on the Ekman upwelling and downwelling from reanalysis and
460 on the Argo fields (e.g. in 2006, the number of Argo floats in the SO is smaller than in later
461 years). The analysis of the relative contribution of heave and water mass processes to θ -S prop-
462 erty changes (Durack and Wijffels 2010) would be a valuable (future) addition to this work, but is
463 beyond the scope of the present study.

464 **5. Summary and conclusions**

465 We use Argo's unprecedented (e.g. spatially distributed with no bias towards summer months)
466 sampling of the Southern Ocean during 2006 – 2013 to describe the recent positions of the Antarc-
467 tic Circumpolar Current's Subantarctic and Polar fronts equatorward of $\sim 60^\circ\text{S}$. We compare and

468 contrast two different methods for locating fronts in the same data set. The first method (Section
469 2b.1) locates three fronts along dynamic height contours, each corresponding to a local maximum
470 in vertically integrated shear (Fig. 1). We term these the Polar front (Pf), Southern (sSAf) and
471 Northern (nSAf) Subantarctic front (from south to north, Fig. 3). The second approach (Section
472 2b.2) locates the same fronts using specific features in the potential temperature field, consis-
473 tent with subduction and/or shoaling of water masses (Table 1), following OWN95. The ACC
474 fronts are associated with strong gradients in temperature and salinity, and with deep-reaching jets
475 (OWN95), hence the two methods are in overall good agreement with each other. Argo DH-frontal
476 locations align well both with local maxima of the zonal and meridional geostrophic transport in
477 the upper 1975 dbar (Fig. 4), and with θ properties that separate regions where the Southern Ocean
478 water mass volume (within the Argo domain) peaks (Fig. 2), i.e. regions with homogeneous θ
479 properties. A local maximum in volume between the Pf and the sSAf is observed around 800 dbar
480 and deeper (Fig. 2) and corresponds to the Upper Circumpolar Deep Water. Another maximum is
481 located between the sSAf and the nSAf, at depths shallower than 1000 dbar (Fig. 2), and aligns
482 with the freshest variety of Antarctic Intermediate Waters that begin to descend north of the Pf
483 (not shown). The agreement between the two methods to locate the fronts also holds locally in
484 most sectors of the Southern Ocean (Fig. 6), and for TS properties along the front (Fig. 7b). Yet
485 the DH-approach is preferable since DH is a vertically integrated quantity, hence not as affected
486 by local phenomena as θ at a specific pressure level (e.g. SAMW formation in the eastern Pacific
487 Ocean). Phenomenological (θ -based) characterizations that align best with the DH fronts follow
488 an isotherm of the $\max(\theta)$ at $p \geq 800$ dbar and of θ at $p = 400$ dbar, for the Pf and SAf (sSAf and
489 nSAf), respectively, and are still not consistent with the DH approach in a few regions, i.e. the
490 eastern Pacific for the nSAf, and around 90°E and in the Atlantic basin for the sSAf and nSAf. In
491 these sectors of the Southern Ocean, the combination of different θ -S criteria may be appropriate

492 to locate the fronts more accurately. Also, the circumpolar θ^* value (of the isotherm at $p=400$
493 dbar) that aligns best with the DH-based sSAf is different from previous studies (Table 1). A main
494 advantage in computing θ^* values along DH- (i.e. streamline-) based fronts here resides in having
495 both the streamfunction and the θ field from the same well-resolved (Argo) dataset and for the
496 same time period (2006 – 2013). Argo frontal locations are consistent overall with findings in
497 Sokolov and Rintoul (2009a), but show local differences with that study, OWN95, and other more
498 recent analyses (Section 2b.1, e.g. at the Kerguelen and Campbell plateaus, the Maurice Ewing
499 Bank, and crossing the East Pacific Rise). Our results focus on the time mean frontal locations.
500 As for movements of the fronts in time, both a DH- and a θ - (contour) based method would be
501 biased by θ variability in the Southern Ocean (Graham et al. 2012; Thompson and Sallee 2012;
502 De Boer et al. 2013; Gille 2014). Large-scale changes in DH and θ contours may, in fact, be due
503 to a warming ocean more than localized shifts in frontal positions. Also, Argo resolution may not
504 be appropriate to detect such changes. The method described recently by Shao et al. (2015) based
505 on altimetry anomalies, can be advantageous to track frontal movements in time.

506 We use Argo four-dimensional coverage of the Southern Ocean equatorward of $\sim 60^\circ\text{S}$ to de-
507 scribe changes in heat and freshwater content in the Southern Ocean during 2006 – 2013 with
508 respect to the time-mean frontal location (Section 4). Heat content increases from 2006 – 2013,
509 in the upper 2000 dbar of the SO (i.e. south of the STf and within the Argo domain), with a signal
510 that is mostly confined to the top 1000 dbar, and is weaker between 1000 and 1500 dbar. The
511 FW anomaly (from the mean) in the top 2000 dbar of the SO is negative in 2009 and 2013, and
512 positive in 2011–2012, with a decrease during the time period of interest in the upper 500 dbar
513 of the n.nSAf region (dominating the SO signal at those pressures), and an increase below 1000
514 dbar. Also, the yearly freshwater anomaly (in the upper 1975 dbar, Fig. 9b) varies spatially in
515 each region considered here (Fig.10).

516 An overall increase of heat and freshwater content is observed for water masses in the range
517 $26.8 \leq \sigma_{\theta} \leq 27.7 \text{ kg m}^{-3}$ (except for the STMW with $26.8 \leq \sigma_{\theta} \leq 26.9 \text{ kg m}^{-3}$, where the FW
518 anomaly is negative at the end of the time series, and positive earlier), with positive (SO) FW
519 anomalies also in 2006–2007 for $\sigma_{\theta} > 27.45 \text{ kg m}^{-3}$ (Fig. 11). This heat and FW estimate in
520 potential density classes (i.e., for water masses) is based on the mean isopycnal location. Yet
521 θ -S properties vary differently on the actual time changing isopycnals (Fig. 12 versus Fig. 13),
522 with anomalies that are opposite in sign (compared to values on the time-mean isopycnal loca-
523 tion) for θ and S in the lighter and denser layers, respectively. This result suggests that heat and
524 freshwater changes from using the mean isopycnal location may be partially related to isopycnal
525 displacement.

526 We observe an overall pressure increase (in time) on isopycnals (Fig. 13i-l) consistent with wind-
527 forced vertical advection by Ekman upwelling and downwelling (Fig. 14) in the SO, n.nSAf and
528 SAf.nPf regions. Such wind-forced vertical advection causes isopycnals to deepen in 2010–2012,
529 contributing to the observed ocean warming signal.

530 Finally, ECMWF ERA-Interim SST shows a statistically significant linear decrease between
531 1979 and 2013 in the general ACC Pf regions at $140 - 170^{\circ}\text{E}$ and $175^{\circ}\text{E} - 120^{\circ}\text{W}$ (not shown),
532 consistent with a long term local cooling of the upper ocean and with the $\min(\theta)$ -based Argo Pf
533 (with the θ^* value by OWN95) being equatorward of the Polar front in OWN95 (Fig. 5), in these
534 sectors of the Southern Ocean.

535 *Acknowledgments.* The Argo data used here were collected and are made freely available by
536 the International Argo Program and by the national programs that contribute to it. The efforts of
537 many international partners in planning and implementing the Argo array are gratefully acknowl-
538 edged. ECMWF ERA-Interim SST data used in this study have been obtained from the ECMWF

539 Data Server. The objectively mapped Argo data were provided by John Gilson. DG was sup-
540 ported through a postdoctoral fellowship by the Joint Institute for the Study of the Atmosphere
541 and Ocean (JISAO) under NOAA Cooperative Agreement NA15OAR4320063, Contribution No.
542 2477. GCJ is supported by NOAA Research and the NOAA Climate Observations Division. The
543 statements, findings, conclusions, and recommendations herein are those of the authors and do
544 not necessarily reflect the views of the National Oceanic and Atmospheric Administration or the
545 Department of Commerce. Thanks to David Ferreira (U. Reading) and Matthew R. Mazloff (SIO)
546 for the discussion about this work. Thanks to the two anonymous reviewers for providing valuable
547 feedback.

752 Brazil and Malvinas confluence. *Deep-Sea Research Part I: Oceanographic Research Papers*,
753 **88**, 1–7, doi:10.1016/j.dsr.2014.02.007.

754 **LIST OF TABLES**

755 **Table 1.** Time mean θ^* ($^{\circ}\text{C}$) from this study (i.e. along the DH-based ACC fronts from
756 the gridded Argo data, Fig. 3), Orsi et al. (1995) (OWN95), and Sokolov and
757 Rintoul (2009a) (SR09, their Table 1). Values for both the middle and northern
758 branch of the SAf in SR09 are in the nSAf column. The standard deviation
759 ($\pm 1\sigma$) along the front is also indicated, as well as water masses related to each
760 criterion (UCDW is Upper Circumpolar Deep Water). 37

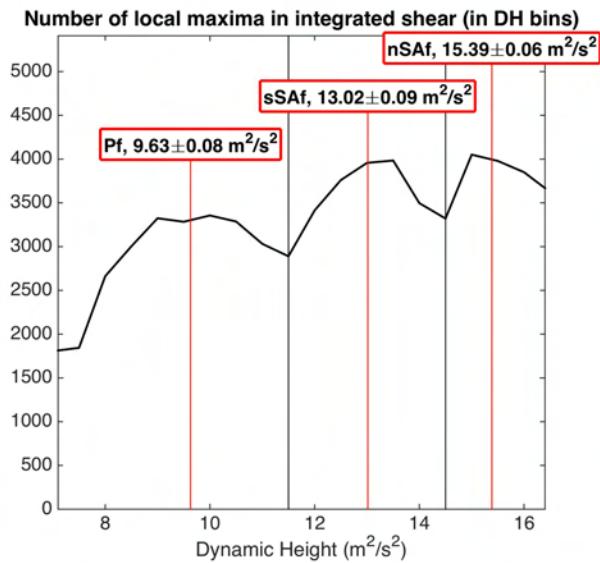

761 TABLE 1. Time mean θ^* ($^{\circ}\text{C}$) from this study (i.e. along the DH-based ACC fronts from the gridded Argo
762 data, Fig. 3), Orsi et al. (1995) (OWN95), and Sokolov and Rintoul (2009a) (SR09, their Table 1). Values for
763 both the middle and northern branch of the SAf in SR09 are in the nSAf column. The standard deviation ($\pm 1\sigma$)
764 along the front is also indicated, as well as water masses related to each criterion (UCDW is Upper Circumpolar
765 Deep Water).

	Pf		sSAf	nSAf

LIST OF FIGURES

766		
767	Fig. 1.	Number of local maxima in vertically integrated geostrophic shear (0 – 1975 dbar) from
768		gridded Argo data, considering all longitudes, latitudes (south of 35.5°S), and months from
769		2006-2013, binned by Dynamic Height (DH). Gray lines separate DH ranges encompass-
770		ing different fronts. Red lines indicate the DH contour assigned to each front (values and
771		standard errors in red boxes, along with abbreviations for the fronts). 40
772	Fig. 2.	(a) Time mean volume in θ (x-axis, °C) and pressure (y-axis, dbar) bins, within the Argo
773		domain south of the Subtropical Front (STf), i.e. gray shaded region in panel b1. The
774		volume in each bin (m^3) is equal to 10 power of the value shaded in color. The mean θ
775		profiles along the DH-based Argo fronts in Fig. 3 (and along the STf) are indicated as thick
776		lines (Pf in blue, sSAf in green, nSAf in red, STf in magenta). (b) Regions of the Argo
777		domain, considered in this study, are shaded gray: (b1) SO (south of the STf), (b2) n.nSAf
778		(between the STf and the nSAf), (b3) SAf.nPf (nSAf to north of the Pf), and (b4) Pf.s (Pf
779		and south). The time mean location of the Argo fronts is color coded as in panel (a). 41
780	Fig. 3.	DH-based ACC fronts from gridded Argo data: frequency of occurrence (dots) during
781		2006 – 2013 (values smaller than 20% are masked out). Light blue to purple dots are for
782		the Polar Front (Pf). Light yellow to green dots are for the Southern Subantarctic Front
783		(sSAf). Light Orange to red dots are for the Northern Subantarctic Front (nSAf). Black
784		lines are, from north to south, the Subantarctic and Polar fronts described in Orsi et al. (1995)
785		(OWN95). Bathymetry (m) shallower than 3500 m is shaded from white to dark brown, in
786		the background. Numbers (in red) are adjacent to some of the main bathymetric features: (1)
787		Drake Passage, (2) Maurice Ewing Bank, (3) Argentine Basin, (4) Atlantic Ridge, (5) SW
788		Indian Ridge, (6) Kerguelen Plateau, (7) Fawn Trough, (8) SE Indian Ridge, (9) Campbell
789		Plateau, (10) Pacific-Antarctic Ridge, (11) Udintsev Fracture Zone, (12) Eltanin Fracture
790		Zone, (13) Menard Fracture Zone, and (14) East Pacific Rise. 42
791	Fig. 4.	DH-based Argo fronts as in Fig. 3, with the background color showing the time mean (a)
792		zonal and (b) meridional baroclinic geostrophic transport per unit meter (m^2s^{-1}), in the
793		upper 1975 dbar, from gridded Argo data. 43
794	Fig. 5.	Argo fronts from θ -criteria (thick lines), using θ^* values consistent with OWN95 (Table 1):
795		x,y locations are averaged in 1 degree longitude bins and in time. Errorbars (dashed lines)
796		include a component related to the bin average and another equal to 1 (temporal) standard
797		deviation of the front meridional location. Bold fonts highlight, in the legend, θ criteria that
798		align best with DH-based fronts. Polar and Subantarctic fronts from OWN95 are shown as
799		black lines. A 5 degree grid is added along the x-axis between 50 – 80°E. 44
800	Fig. 6.	DH-based (thick lines) and θ -based (thin lines) Argo fronts (with θ^* values computed along
801		the DH-based fronts, Table 1): x,y locations are averaged in 1 degree longitude bins and in
802		time. Errorbars (dashed lines), include a component related to the bin average and another
803		equal to 1 (temporal) standard deviation of the front meridional location. A 5 degree grid is
804		added along the x-axis between 50 – 80°E. 45
805	Fig. 7.	Comparison of time mean θ -S diagrams along the DH-based Argo fronts in Fig. 3 (black
806		edge dots in panel (a) and (b)), with those from the θ -based Argo fronts (in bold) in Fig.
807		5 (gray edge dots in panel (a)), and in Fig. 6 (gray edge dots in panel (b)), with θ from
808		colder to warmer along the Pf, sSAf, and nSAf. Errorbars (black solid lines) are indicated
809		for the DH-based fronts, consistent with the error on the DH contour choice associated with
810		each front (Fig. 1). In both panels, dotted lines indicate θ^* -S* values described in OWN95.
811		Dashed lines indicate θ^* values used to locate the θ -based fronts (different between panel

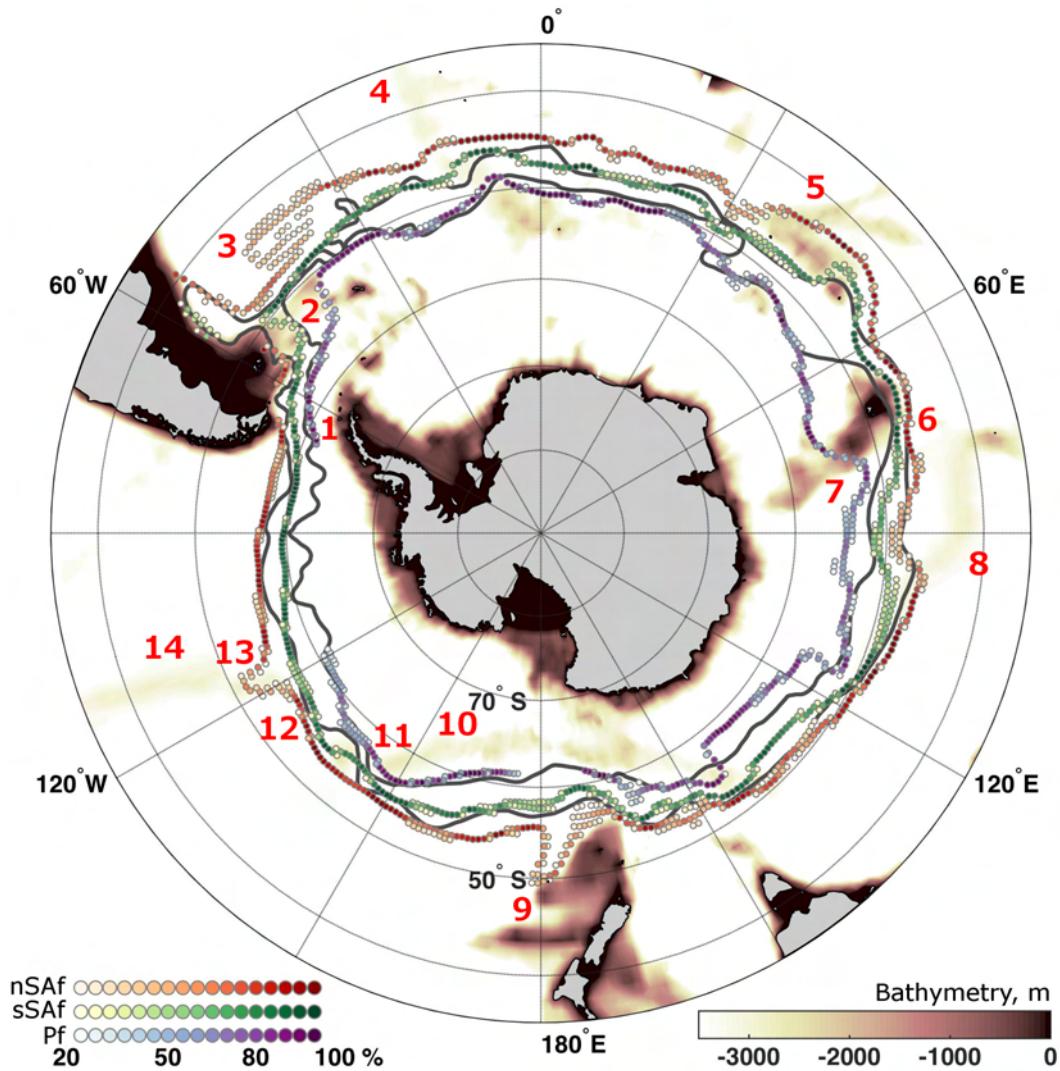

812	(a) and (b)). In panel (a), dashed lines coincide with dotted ones, since θ^* values are from	
813	OWN95. In panel (b), dashed lines are for θ^* computed along DH-based fronts. Dot colors	
814	represent mean pressure (dbar) at the θ -S values along the fronts.	46
815	Fig. 8. Yearly θ -S diagram along the Argo (a) nSAf and (b) Pf in Fig. 3. Errorbars are shown	
816	around each dot. Gray contours indicate isopycnals. The 200, 400, 600 dbar pressure levels	
817	are marked, with pressure increasing from warmer to colder for the nSAf and from fresher	
818	to saltier for the Pf.	47
819	Fig. 9. Yearly (left) heat and (right) freshwater content anomalies from the 2006–2013 time mean,	
820	in different regions of the SO (legend in panel b, and maps in Fig. 2b) and for different	
821	pressure ranges (tops and bottoms of pressure layers are indicated in the title). Dots signify	
822	that the yearly value is larger than its standard error. Freshwater values are in cm, after	
823	normalizing the volume of freshwater by the area of the SO within the Argo domain ($6.001 \cdot$	
824	10^{13} m^2). The legend in the left panels indicates the ocean volume in each region.	48
825	Fig. 10. Maps of yearly freshwater content (m) anomalies from the 2006–2013 time mean, for the	
826	0 – 1975 dbar pressure range, with zero contour (thin black line). Black dots signify that the	
827	yearly value is smaller than its standard error. DH-based Argo fronts are indicated as thick	
828	lines as in Fig. 2b.	49
829	Fig. 11. Yearly (top) heat and (bottom) freshwater content anomalies from the 2006–2013 time mean	
830	in different regions of the SO (same regions as in Fig. 9) and in 0.05 kg m^{-3} thick potential	
831	density classes (y-axis). Values are based on the time mean location of isopycnals. Fresh-	
832	water values follow Fig. 9. Black contours: pressure on isopycnals. Years since 2000	
833	are indicated on the x-axis.	50
834	Fig. 12. Yearly anomalies from the 2006–2013 time mean of (top) potential temperature, (middle)	
835	salinity, and (bottom) potential density on the mean locations of a set of isopycnals (y-axis,	
836	kg m^{-3}). Regions follow Fig. 9. Black contours: pressure on isopycnals. Years since 2000	
837	are indicated on the x-axis.	51
838	Fig. 13. Following Fig. 12, but on the actual (time varying) isopycnal locations. Bottom panels show	
839	pressure anomalies on isopycnals.	52
840	Fig. 14. Comparison of pressure changes on isopycnals (a) estimated from ECMWF ERA-Interim	
841	wind stress curl (i.e. Ekman upwelling and downwelling), and (b-d) observed by Argo in	
842	different regions (following Fig. 9). Changes are indicated as the cumulative sum of monthly	
843	dp (i.e. difference in pressure between month i and month i-1) since the beginning of 2006	
844	(to the end of the year in the x-axis). In panels (b-d), light to dark shades are for lighter	
845	to denser isopycnals. Also, in panels (b-d), dashed lines indicate the estimate from Ekman	
846	upwelling and downwelling shown in panel (a).	53

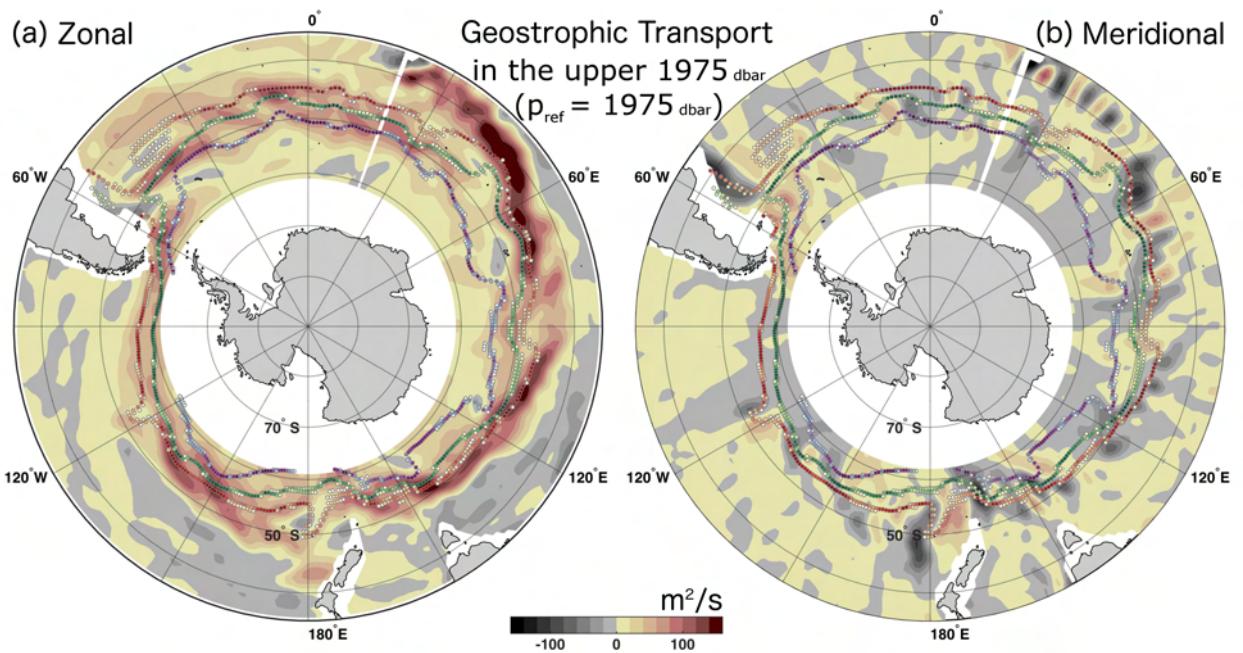

847 FIG. 1. Number of local maxima in vertically integrated geostrophic shear (0 – 1975 dbar) from gridded Argo
 848 data, considering all longitudes, latitudes (south of 35.5°S), and months from 2006-2013, binned by Dynamic
 849 Height (DH). Gray lines separate DH ranges encompassing different fronts. Red lines indicate the DH contour
 850 assigned to each front (values and standard errors in red boxes, along with abbreviations for the fronts).

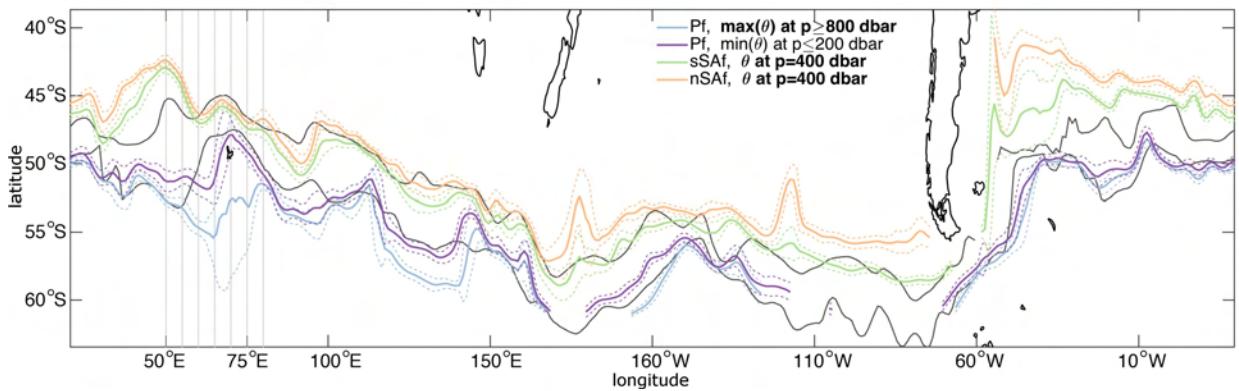

851 FIG. 2. (a) Time mean volume in θ (x-axis, $^{\circ}\text{C}$) and pressure (y-axis, dbar) bins, within the Argo domain
 852 south of the Subtropical Front (STf), i.e. gray shaded region in panel b1. The volume in each bin (m^3) is equal
 853 to 10 power of the value shaded in color. The mean θ profiles along the DH-based Argo fronts in Fig. 3 (and
 854 along the STf) are indicated as thick lines (Pf in blue, sSAf in green, nSAf in red, STf in magenta). (b) Regions
 855 of the Argo domain, considered in this study, are shaded gray: (b1) SO (south of the STf), (b2) n.nSAf (between
 856 the STf and the nSAf), (b3) SAf.nPf (nSAf to north of the Pf), and (b4) Pf.s (Pf and south). The time mean
 857 location of the Argo fronts is color coded as in panel (a).

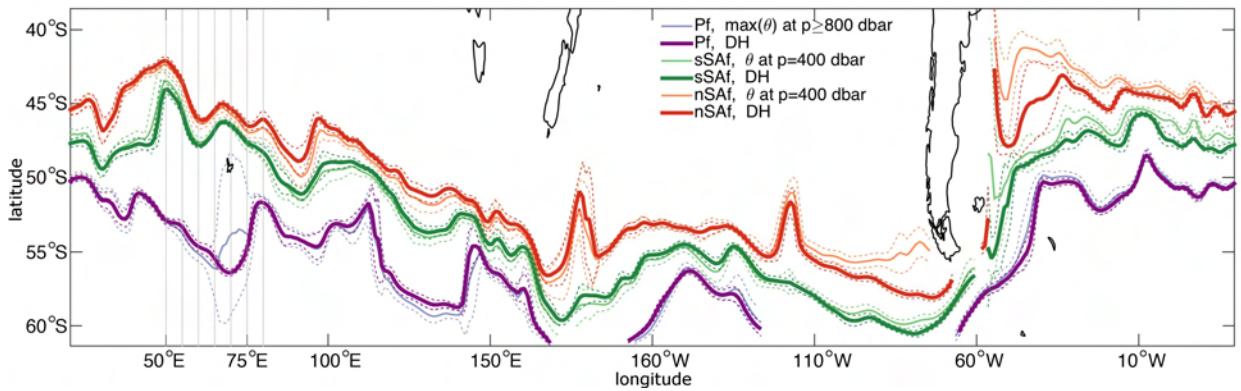

858 FIG. 3. DH-based ACC fronts from gridded Argo data: frequency of occurrence (dots) during 2006 – 2013
 859 (values smaller than 20% are masked out). Light blue to purple dots are for the Polar Front (Pf). Light yellow
 860 to green dots are for the Southern Subantarctic Front (sSAf). Light Orange to red dots are for the Northern
 861 Subantarctic Front (nSAf). Black lines are, from north to south, the Subantarctic and Polar fronts described in
 862 Orsi et al. (1995) (OWN95). Bathymetry (m) shallower than 3500 m is shaded from white to dark brown, in the
 863 background. Numbers (in red) are adjacent to some of the main bathymetric features: (1) Drake Passage, (2)
 864 Maurice Ewing Bank, (3) Argentine Basin, (4) Atlantic Ridge, (5) SW Indian Ridge, (6) Kerguelen Plateau, (7)
 865 Fawn Trough, (8) SE Indian Ridge, (9) Campbell Plateau, (10) Pacific-Antarctic Ridge, (11) Udintsev Fracture
 866 Zone, (12) Eltanin Fracture Zone, (13) Menard Fracture Zone, and (14) East Pacific Rise.

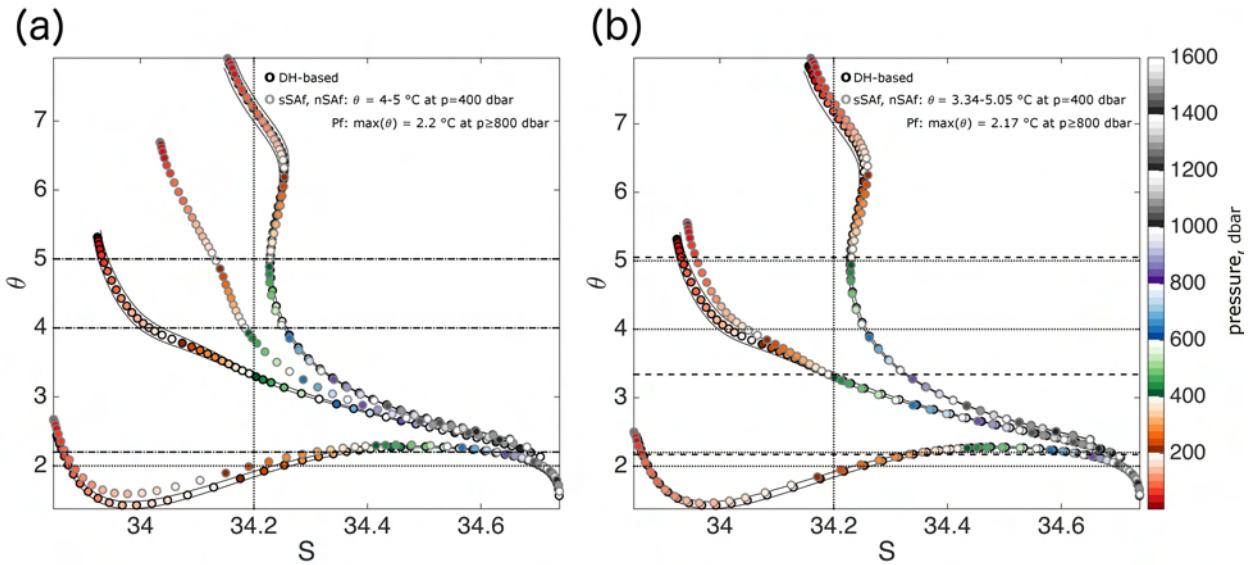

867 FIG. 4. DH-based Argo fronts as in Fig. 3, with the background color showing the time mean (a) zonal and
 868 (b) meridional baroclinic geostrophic transport per unit meter (m^2s^{-1}), in the upper 1975 dbar, from gridded
 869 Argo data.

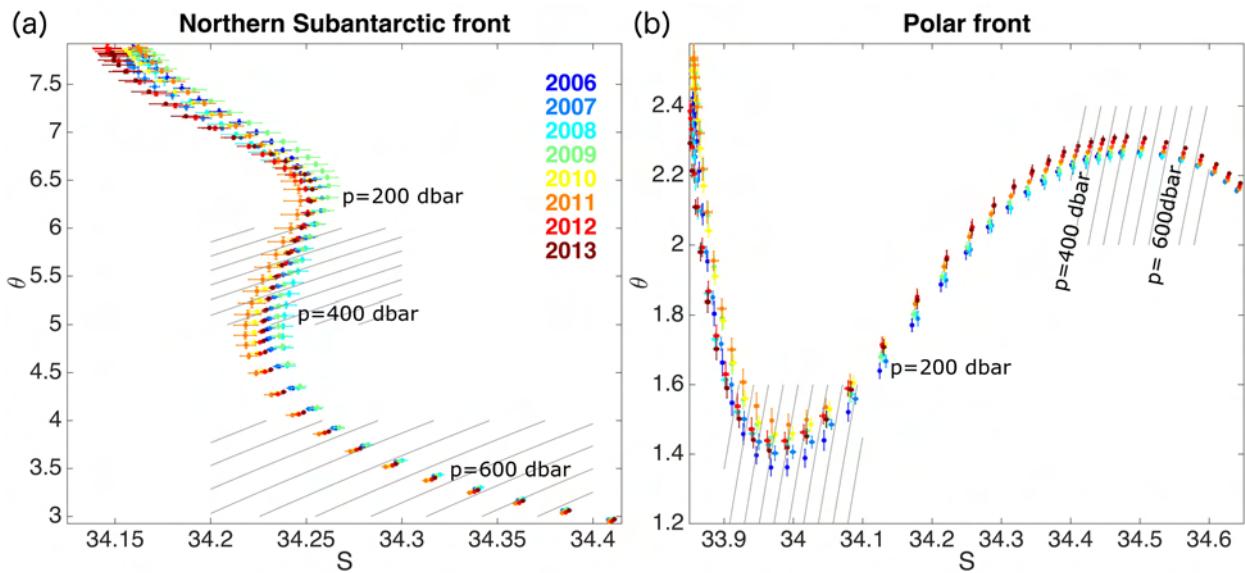

870 FIG. 5. Argo fronts from θ -criteria (thick lines), using θ^* values consistent with OWN95 (Table 1): x,y
 871 locations are averaged in 1 degree longitude bins and in time. Errorbars (dashed lines) include a component
 872 related to the bin average and another equal to 1 (temporal) standard deviation of the front meridional location.
 873 Bold fonts highlight, in the legend, θ criteria that align best with DH-based fronts. Polar and Subantarctic fronts
 874 from OWN95 are shown as black lines. A 5 degree grid is added along the x-axis between 50 – 80°E.

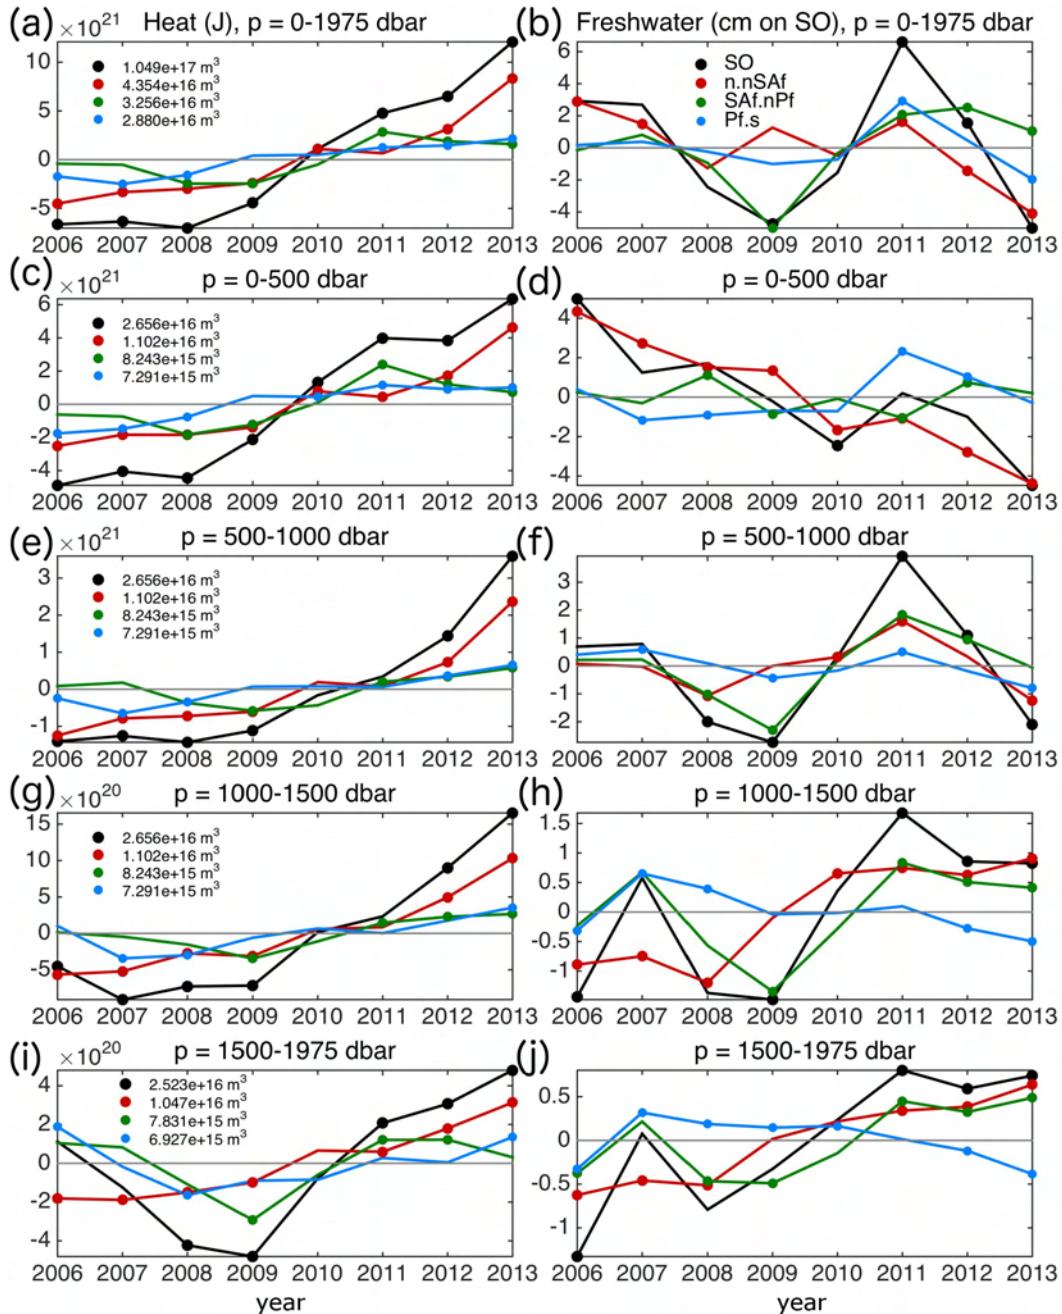

875 FIG. 6. DH-based (thick lines) and θ -based (thin lines) Argo fronts (with θ^* values computed along the
 876 DH-based fronts, Table 1): x,y locations are averaged in 1 degree longitude bins and in time. Errorbars (dashed
 877 lines), include a component related to the bin average and another equal to 1 (temporal) standard deviation of
 878 the front meridional location. A 5 degree grid is added along the x-axis between 50 – 80°E.

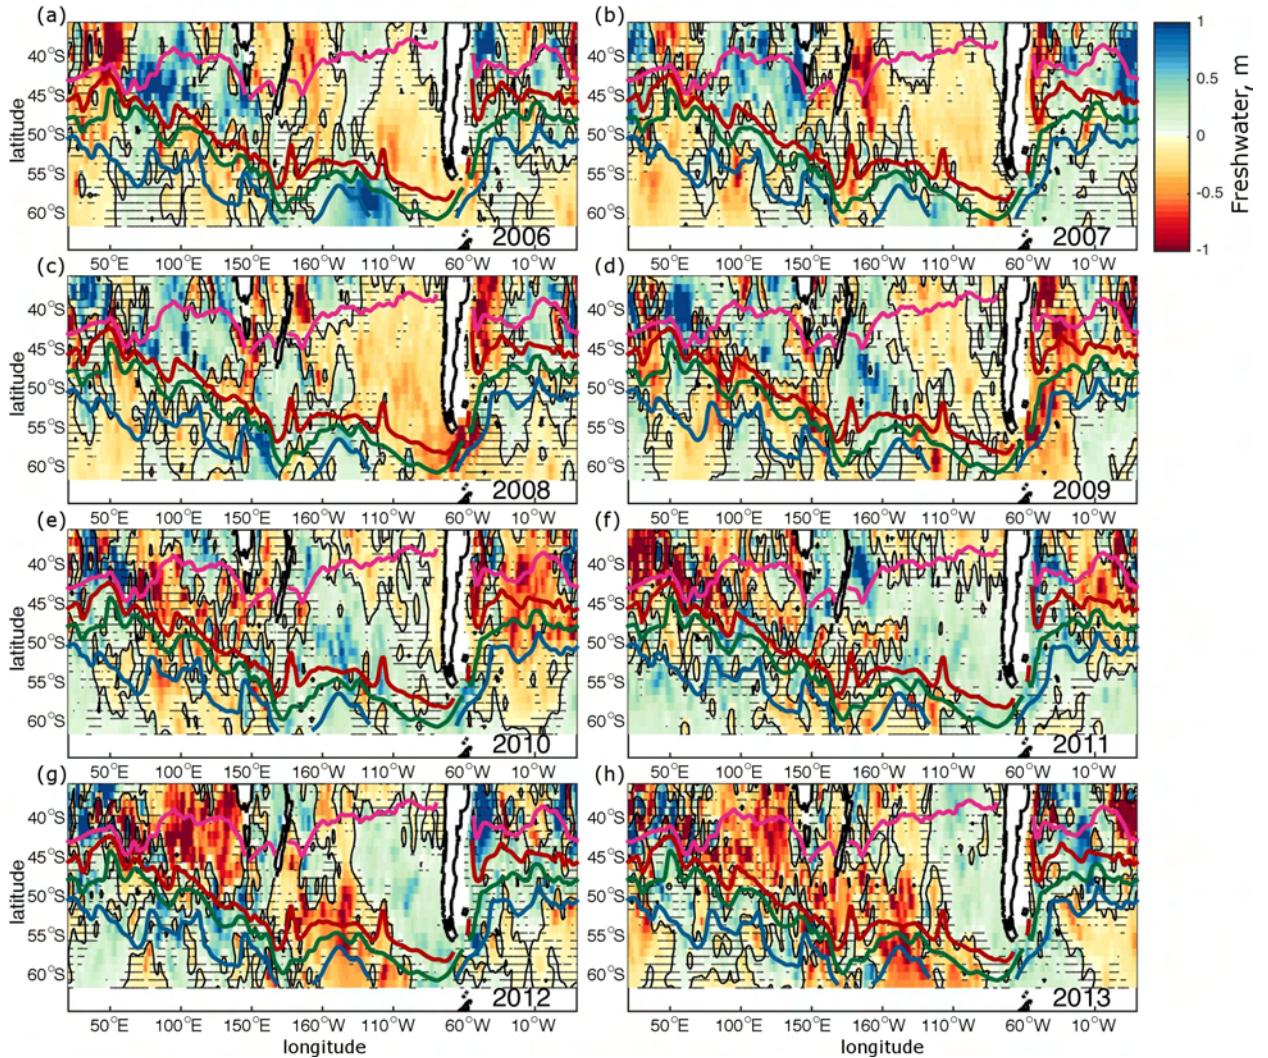

879 FIG. 7. Comparison of time mean θ -S diagrams along the DH-based Argo fronts in Fig. 3 (black edge dots in
 880 panel (a) and (b)), with those from the θ -based Argo fronts (in bold) in Fig. 5 (gray edge dots in panel (a)), and
 881 in Fig. 6 (gray edge dots in panel (b)), with θ from colder to warmer along the Pf, sSAf, and nSAf. Errorbars
 882 (black solid lines) are indicated for the DH-based fronts, consistent with the error on the DH contour choice
 883 associated with each front (Fig. 1). In both panels, dotted lines indicate θ^* -S* values described in OWN95.
 884 Dashed lines indicate θ^* values used to locate the θ -based fronts (different between panel (a) and (b)). In panel
 885 (a), dashed lines coincide with dotted ones, since θ^* values are from OWN95. In panel (b), dashed lines are
 886 for θ^* computed along DH-based fronts. Dot colors represent mean pressure (dbar) at the θ -S values along the
 887 fronts.

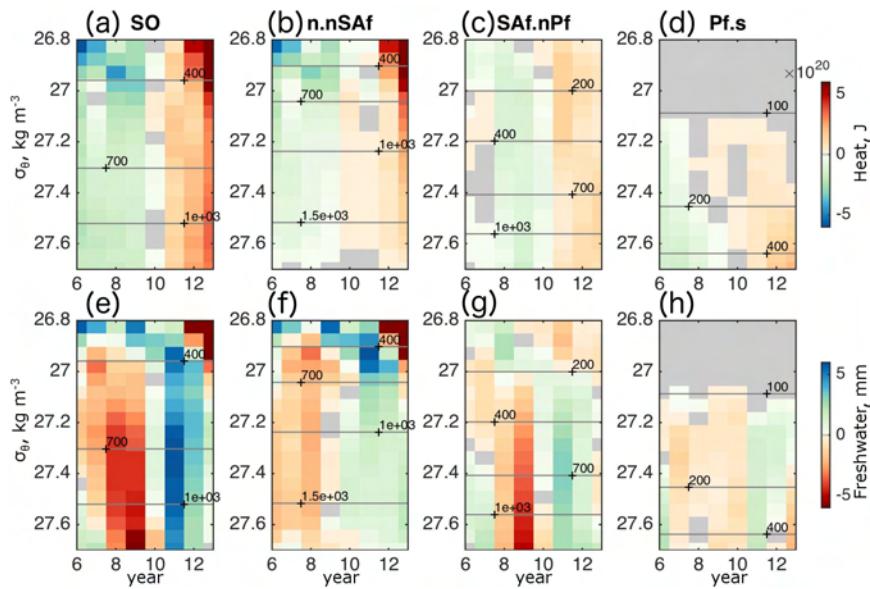

888 FIG. 8. Yearly θ -S diagram along the Argo (a) nSAf and (b) Pf in Fig. 3. Errorbars are shown around each dot.
 889 Gray contours indicate isopycnals. The 200, 400, 600 dbar pressure levels are marked, with pressure increasing
 890 from warmer to colder for the nSAf and from fresher to saltier for the Pf.

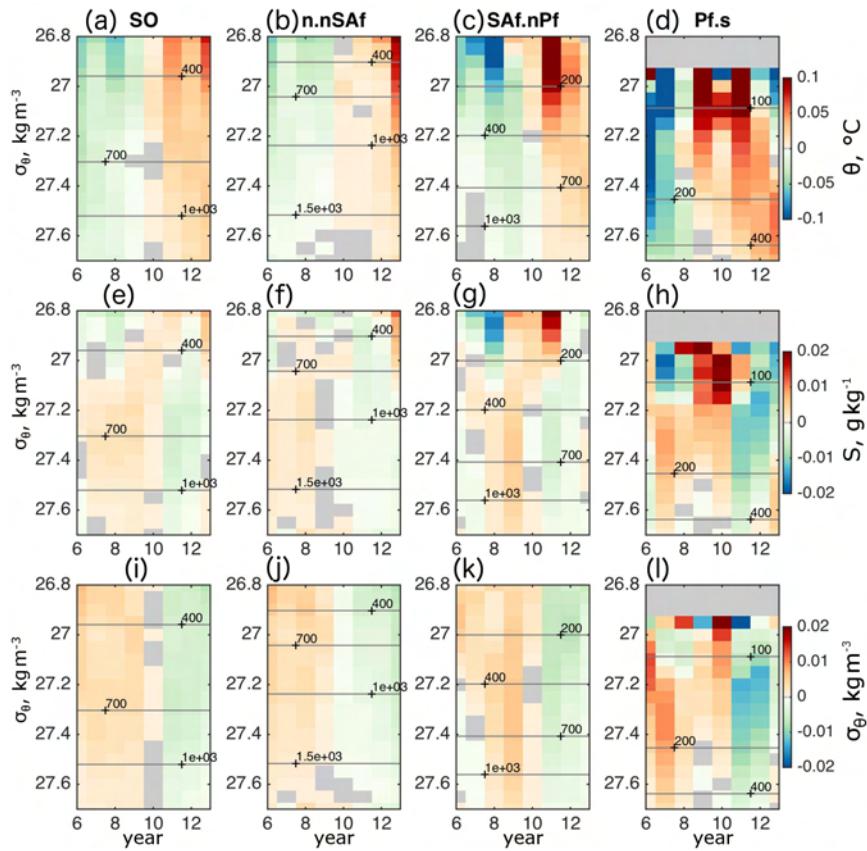

891 FIG. 9. Yearly (left) heat and (right) freshwater content anomalies from the 2006–2013 time mean, in different
 892 regions of the SO (legend in panel b, and maps in Fig. 2b) and for different pressure ranges (tops and bottoms
 893 of pressure layers are indicated in the title). Dots signify that the yearly value is larger than its standard error.
 894 Freshwater values are in cm, after normalizing the volume of freshwater by the area of the SO within the Argo
 895 domain ($6.001 \cdot 10^{13} \text{ m}^2$). The legend in the left panels indicates the ocean volume in each region.

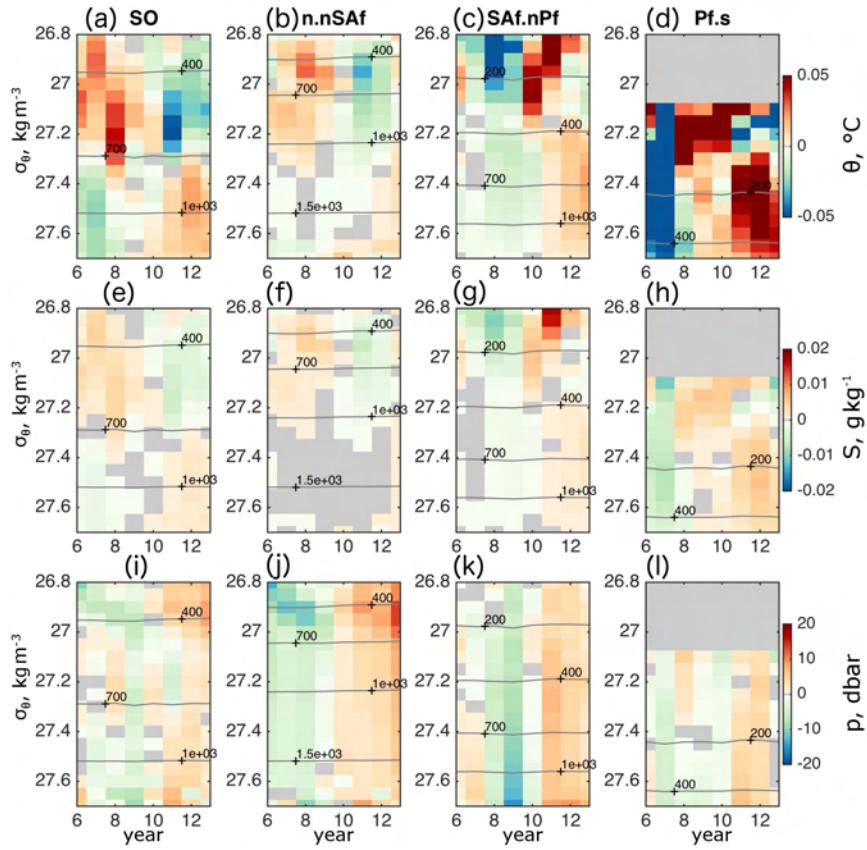

896 FIG. 10. Maps of yearly freshwater content (m) anomalies from the 2006–2013 time mean, for the 0 – 1975
 897 dbar pressure range, with zero contour (thin black line). Black dots signify that the yearly value is smaller than
 898 its standard error. DH-based Argo fronts are indicated as thick lines as in Fig. 2b.

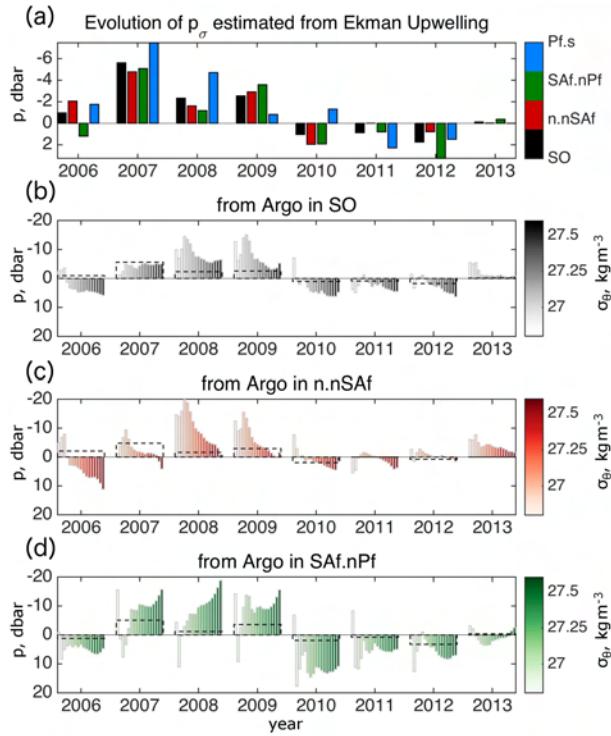

899 FIG. 11. Yearly (top) heat and (bottom) freshwater content anomalies from the 2006–2013 time mean in
 900 different regions of the SO (same regions as in Fig. 9) and in 0.05 kg m^{-3} thick potential density classes (y-
 901 axis). Values are based on the time mean location of isopycnals. Freshwater values follow Fig. 9. Black
 902 contours: pressure on isopycnals. Years since 2000 are indicated on the x-axis.

903 FIG. 12. Yearly anomalies from the 2006–2013 time mean of (top) potential temperature, (middle) salinity,
 904 and (bottom) potential density on the mean locations of a set of isopycnals (y-axis, kg m^{-3}). Regions follow Fig.
 905 9. Black contours: pressure on isopycnals. Years since 2000 are indicated on the x-axis.

906 FIG. 13. Following Fig. 12, but on the actual (time varying) isopycnal locations. Bottom panels show pressure
 907 anomalies on isopycnals.

908 FIG. 14. Comparison of pressure changes on isopycnals (a) estimated from ECMWF ERA-Interim wind stress
 909 curl (i.e. Ekman upwelling and downwelling), and (b-d) observed by Argo in different regions (following Fig.
 910 9). Changes are indicated as the cumulative sum of monthly dp (i.e. difference in pressure between month i
 911 and month $i-1$) since the beginning of 2006 (to the end of the year in the x-axis). In panels (b-d), light to dark
 912 shades are for lighter to denser isopycnals. Also, in panels (b-d), dashed lines indicate the estimate from Ekman
 913 upwelling and downwelling shown in panel (a).
